ABSTRACT

The inverse cascade in MHD turbulence plays a crucial role in various astrophysical processes such as galaxy cluster formation, solar and stellar dynamo mechanisms, and the evolution of primordial magnetic fields in the early universe. A standard numerical approach involves injecting magnetic helicity at intermediate length scales to generate a secondary, time-dependent spectral peak that gradually propagates toward larger scales. Previous simulations have already suggested a resistive dependence of inverse transfer rates and demonstrated the significant influence of magnetic helicity flux density ϵ_H on this process. On dimensional grounds, we have $E_M(k, t) = C_H \epsilon_H^{2/3} k^{-1}$ where C_H represents a potentially universal dimensionless coefficient analogous to the Kolmogorov constant. We present a summary of the 25 distinct simulations conducted with the PENCIL CODE, systematically varying the forcing wavenumber k_f , magnetic Prandtl number Pr_M , grid resolution N^3 , and Lundquist number Lu . We obtained C_H and corresponding error bars by calculating the compensated spectrum and investigated its dependence with Lu and k_f . For the $C_H - Lu$ relationship, we observe strong correlations with power-law exponents of 1 and 2/3. In contrast, we find no significant correlation between C_H and k_f .

Keywords: Magnetic fields (994); Hydrodynamics (1963)

1. INTRODUCTION

Turbulent flows involve a large range of length scales. Due to the presence of nonlinearities in the hydrodynamic equations, there can be energy transfer between different length scales. This energy transfer is typically local in wavenumber space and therefore one tends to talk about an energy *cascade*. In ordinary three-dimensional hydrodynamic turbulence, energy flows from large to small scales, which is referred to as a direct or forward cascade. In the presence of magnetic fields, however, turbulence can behave very differently. In particular, there is the possibility of an inverse cascade if the magnetic field is helical. This was first explored by Frisch et al. (1975) and Pouquet et al. (1976), who associated the inverse cascade with the conservation of magnetic helicity.

The early work on inverse transfers in hydromagnetic turbulence is significant in the context of astrophysical magnetism. It was known that large-scale magnetic fields in stars and galaxies can be caused by cyclonic turbulence (Parker 1955, 1971). This means that the

combination of radially inward directed gas density gradients and global rotation can cause negative kinetic helicity of the turbulence in the northern hemisphere and positive kinetic helicity in the southern hemisphere. Such flows render a nonmagnetic state unstable to small amplitude and large wavelength perturbations (Moffatt 1970, 1978). This was explained in terms of what is called the α effect (Steenbeck et al. 1966), where α is a pseudoscalar proportional to the negative kinetic helicity in the evolution equations for the mean magnetic field at sufficiently high conductivity.

The possibility of an inverse cascade of magnetic helicity toward larger scales was studied numerically by injecting magnetic helicity at intermediate length scales. This led to the emergence of a second, time-dependent peak in the magnetic energy spectrum that gradually propagated toward smaller wavenumbers, corresponding to progressively larger length scales (Pouquet et al. 1976). The first peak stays fixed and reflects the helicity injection wavenumber. A similar behavior can also

be seen in simulations with finite kinetic helicity forcing (Brandenburg 2001) instead of the magnetic forcing.

While the simulations with kinetic forcing explained some important properties of astrophysical magnetism, they still have the problem of displaying a resistive decrease of the resulting mean magnetic field strengths with increasing magnetic Reynolds number (Del Sordo et al. 2013; Rincon 2021). Because of this, it still remains difficult to explain the large-scale magnetic field generation in astrophysically relevant systems at large magnetic Reynolds numbers. There was even evidence for a resistivity-dependent speed of the inverse transfer.

A possible solution to the problem of resistively limited large-scale magnetic field generation was thought to be the connected with magnetic helicity conservation within the domain. This was pointed out by Gruzinov & Diamond (1996), who argued that in the absence of magnetic helicity fluxes, as is the case in periodic domains, the magnetic helicity from the small-scale field leads to an adverse contribution to the α effect that is proportional to the current helicity density (Pouquet et al. 1976). These ideas emerged after the resistively slow saturation behavior of the magnetic field in the three-dimensional turbulence simulations of Brandenburg (2001) was understood to be a consequence of magnetic helicity conservation (Blackman & Field 2002); see Brandenburg et al. (2002).

Significant effort has gone into the study of magnetic helicity fluxes (Vishniac & Cho 2001; Subramanian & Brandenburg 2004, 2006; Hubbard & Brandenburg 2011, 2012; Del Sordo et al. 2013; Rincon 2021). However, not only the saturation magnetic field strength, but also the magnetic helicity fluxes themselves continue to depend on the magnetic Reynolds number until the present day. In the recent work of Brandenburg & Vishniac (2025), it was shown that the spatial magnetic helicity fluxes between regions of different magnetic helicity density can be equal to the spectral ones from small to large length scales. This motivates a fresh look at the dependence of the speed of magnetic helicity fluxes on the magnetic Reynolds number.

A resistive dependence of the speed of inverse transfer in the inertial range of magnetically forced turbulence has already previously been seen in the simulations of Brandenburg et al. (2002). This was surprising, because in turbulence, the microphysical viscosity and resistivity were thought to not play a role and should not affect the turbulence as a whole. To reexamine this possibility, it is useful to adopt a more idealized settings where magnetic helicity is injected directly at intermediate length scales, just as it was done in the original work of Pouquet et al.

(1976). Similar models have also been considered on other occasions (Malapaka & Müller 2013).

One of the key points of the present investigation is the analysis of the dimensionally motivated law for the spectral magnetic energy evolution. One may argue that the main physical process governing the system is the magnetic helicity flux density ϵ_H , which has units of magnetic helicity density per unit time. Assuming that the magnetic field is characterized by the Alfvén velocity $v_A = B_{\text{rms}}/\sqrt{\mu_0\rho_0}$, where B_{rms} is the rms magnetic field, μ_0 is the vacuum permeability, and ρ_0 is the background density, the magnetic helicity has units of $v_A^2\xi_M$, where ξ_M is a characteristic magnetic length scale, so the units are cm^3s^{-2} . The units of the magnetic helicity flux are therefore cm^3s^{-3} . We employ the magnetic energy spectrum defined such that $\int E_M(k, t) dk = v_A^2/2$, where k is the wavenumber. Since k has units of cm^{-1} , the units of $E_M(k, t)$ are cm^3s^{-2} . Expressing $E_M(k, t)$ as powers a and b of ϵ_H and k , respectively, we have $E_M(k, t) \propto \epsilon_H^a k^b$. On dimensional grounds, we have $a = 2/3$ and $b = -1$, i.e.,

$$E_M(k, t) = C_H \epsilon_H^{2/3} k^{-1}, \quad (1)$$

where C_H is a nondimensional coefficient. Assuming that this is indeed the relevant phenomenology, it is in principle possible that C_H is a universal constant, just like the Kolmogorov constant, which is the nondimensional constant in the kinetic energy spectrum in terms of a $2/3$ power of the kinetic energy flux and a $-5/3$ power of the wavenumber. Alternatively, it is possible that C_H is different from case to case. This will be the possibility favored by the present simulations.

It should be pointed out that there is another possible phenomenology for a k^{-1} spectrum, which assumes the presence of a large-scale magnetic field with Alfvén speed v_A , so $E_M(k) \propto v_A^2 k^{-1}$ (Ruzmaikin & Shukurov 1982; Kleeorin & Rogachevskii 1994). This alternative is independent of the presence of magnetic helicity and may therefore not be relevant to us, because there would be no inverse cascade without net helicity. Also, in our case, the k^{-1} power law describes the envelope of the inversely cascading peak of the spectrum rather than a continuous k^{-1} spectrum over an extended range. The latter is expected when there is instead an already existing large-scale magnetic field characterized by v_A ; see Equation (31) of Kleeorin & Rogachevskii (1994). This is why those authors quoted the simulations of the preprint of Brandenburg et al. (1996); see their Figures 17 and 18.

This present paper is organized as follows. In Section 2, we begin by presenting the model, characteristic indicators, and initial conditions for direct numerical

simulations (DNS) of the forced helical MHD equations. In Section 3, we present the results derived from our numerical simulations, offering insights into the dependency of C_H with respect to Lundquist number Lu and forcing wavenumber k_f . Finally, we conclude our findings and discuss extending investigations in Section 4.

2. NUMERICAL SIMULATIONS

2.1. Governing Equations in Helically Forced MHD

In this section, we consider MHD equations with an isothermal equation of state in a periodic domain with helical magnetic forcing. An isothermal equation of state is characterized by gas pressure p proportional to the gas density ρ with $p = \rho c_s^2$, where c_s is a constant isothermal sound speed. To guarantee solenoidality, the magnetic field could be expressed in magnetic vector potential \mathbf{A} , i.e., $\mathbf{B} = \nabla \times \mathbf{A}$. We solve the governing equations with the evolution equations for \mathbf{A} and the velocity field \mathbf{u} as follows

$$\frac{\partial \mathbf{A}}{\partial t} = \mathbf{u} \times \mathbf{B} - \eta \mu_0 \mathbf{J} + \mathcal{E}_{\text{ext}}, \quad (2)$$

$$\frac{D\mathbf{u}}{Dt} = -c_s^2 \nabla \ln \rho + \frac{1}{\rho} [\mathbf{J} \times \mathbf{B} + \nabla \cdot (2\nu \rho \mathbf{S})], \quad (3)$$

$$\frac{D \ln \rho}{Dt} = -\nabla \cdot \mathbf{u}, \quad (4)$$

where $D/Dt = \partial/\partial t + \mathbf{u} \cdot \nabla$ is the advective derivative, \mathcal{E}_{ext} is the external forcing function, $\mathbf{J} = \nabla \times \mathbf{B}/\mu_0$ is the current density, η is the magnetic diffusivity, ν is the kinematic viscosity, and \mathbf{S} is the traceless rate-of-strain tensor with the following components

$$S_{ij} = \frac{1}{2}(\partial_i u_j + \partial_j u_i) - \frac{1}{3} \delta_{ij} \nabla \cdot \mathbf{u}. \quad (5)$$

Owing to the absence of boundaries, and using volume averages indicated by angle brackets, the magnetic helicity equation is then given by

$$\frac{d}{dt} \langle \mathbf{A} \cdot \mathbf{B} \rangle = -2\eta \mu_0 \langle \mathbf{J} \cdot \mathbf{B} \rangle + 2 \langle \mathcal{E}_{\text{ext}} \cdot \mathbf{B} \rangle, \quad (6)$$

where the first term on the right-hand side quantifies the resistive losses and the second term the magnetic helicity injection through the forcing function. If there were a statistically steady state, the two terms on the right-hand side of Equation (6) should be equal. In addition, owing to a stochastic nature of the forcing, the determination of $2 \langle \mathcal{E}_{\text{ext}} \cdot \mathbf{B} \rangle$ is less accurate. Therefore, in our numerical analysis, we estimate the magnetic helicity flux through the dissipative term, i.e., $\epsilon_H = 2\eta \mu_0 \langle \mathbf{J} \cdot \mathbf{B} \rangle$.

2.2. The Model

We solve Equations (2)–(4) with periodic boundary conditions using the PENCIL CODE, which employs sixth-order finite differences and a third-order accurate time stepping scheme. We compare runs with different resolutions using up to $N^3 = 1024^3$ meshpoints. We use a 5th-order upwind derivative operator for the advection term Dobler et al. (2006) to damp spatial oscillations at the Nyquist wavenumber. Each simulation is further characterized by the Lundquist number Lu , which is defined as

$$Lu = \frac{B_{\text{rms}}}{\eta k_p} = \frac{v_A \xi_M}{\eta}, \quad (7)$$

where k_p is the peak forcing wavenumber of the spectrum, $v_A = B_{\text{rms}}/\sqrt{\mu_0/\rho_0}$ is the Alfvén speed based on the rms magnetic field, and $\xi_M = 1/k_p$ is a magnetic correlation length, which is also characterized by

$$\xi_M(t) = \frac{\int k^{-1} E_M(k) dk}{\int E_M(k) dk}. \quad (8)$$

The simulations are further characterized by the fluid and magnetic Reynolds numbers,

$$Re = \frac{u_{\text{rms}} \xi_M}{\nu} = \frac{u_{\text{rms}}}{\nu k_p}, \quad Re_M = \frac{u_{\text{rms}} \xi_M}{\eta} = \frac{u_{\text{rms}}}{\eta k_p}, \quad (9)$$

where u_{rms} is the rms value of the resulting velocity field and the magnetic Prandtl number is given by $Pr_M = \nu/\eta = Re_M/Re$. The forcing function \mathcal{E}_{ext} in Equation (2) is randomly chosen and δ -correlated in time, defined as

$$\mathbf{f}(x, t) = \text{Re} \left\{ f_0 c_s (|\mathbf{k}| c_s / \delta t)^{1/2} \mathbf{f}_{\mathbf{k}(t)} e^{i[\mathbf{k}(t) \cdot \mathbf{x} + \phi(t)]} \right\}, \quad (10)$$

where f_0 is a non-dimensional forcing amplitude, δt is the length of the time step, $-\pi < \phi(t) < \pi$ is a random phase, and $\mathbf{k}(t)$ is a randomly chosen from a pre-generated set of wavevectors in a narrow band of width δk around a given forcing wavenumber with an average value k_f , i.e.,

$$k_f - \delta k/2 \leq |\mathbf{k}(t)| < k_f + \delta k/2. \quad (11)$$

In all cases, the amplitude of the forcing function is $f_0 = 0.01$, which results in a Mach number u_{rms}/c_s of around 0.05. Transverse helical waves are produced via (Brandenburg & Subramanian 2005)

$$\mathbf{f}_{\mathbf{k}} = \mathbf{R} \cdot \mathbf{f}_{\mathbf{k}}^{\text{nohel}}, \quad R_{ij} = \frac{\delta_{ij} - i\sigma \epsilon_{ijk} \hat{k}_k}{\sqrt{1 + \sigma^2}}, \quad (12)$$

where σ is a measure of the helicity of the forcing. In our case, we keep $\sigma = 1$ for positive maximum helicity of the forcing function, and

$$\mathbf{f}_{\mathbf{k}}^{\text{nohel}} = (\mathbf{k} \times \hat{\mathbf{e}})/\sqrt{k^2 - (\mathbf{k} \cdot \hat{\mathbf{e}})^2} \quad (13)$$

Table 1. Overview of simulation runs in this work.

is a non-helical forcing function, where \hat{e} is an arbitrary unit vector that is not aligned with \mathbf{k} .

Our initial conditions are $\mathbf{A} = \mathbf{u} = \ln(\rho/\rho_0) = 0$, where ρ_0 is the mean density, which is a constant owing to mass conservation and the use of periodic boundary conditions. Starting with the first time step, $\mathbf{A}(\mathbf{x}, t)$ begins to evolve away from zero. The resulting Lorentz force $\mathbf{J} \times \mathbf{B}$ then drives \mathbf{u} away from zero, and finally, finite compressions with $\nabla \cdot \mathbf{u} \neq 0$ drive $\ln(\rho/\rho_0)$ away from zero.

3. RESULTS

In Table 1, we present a summary of the runs discussed in this paper. Figure 1 illustrates the inverse cascade process using simulation A1, showing energy spectra at different time points with red dots marking the calculated spectral peaks, which clearly reveal the characteristic envelope of the inverse cascade evolution. Note, the spectrum peak on the right side is caused by the injection of helical forcing, which occurs at k_f .

We separated our simulations into subsets so that we can examine the dependence of C_H with respect to the various variables (e.g., k_f , Pr_M , N^3 , and Lu). Our primary focus is to cover a range of values of Lu from 5 to

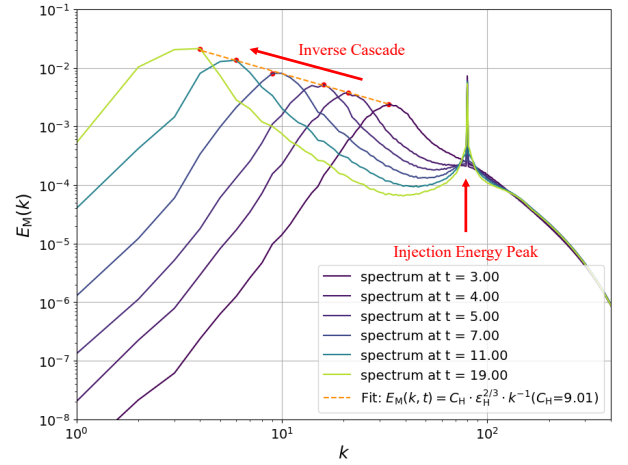

Figure 1. An illustration of estimating C_H using simulation A1. The red solid dots refer to the energy spectrum peak at each timestep. The orange dashed line refers to the fitted curve from Equation (1) with $R^2 = 0.99$.

54, but we also altered Re and Re_M so as to obtain a range of Pr_M from $2/5$ to 2 to examine whether it plays a role in the inverse cascade process of evolving helical

Figure 2. Helicity dissipation decay with respect to time for simulation runs A1 (black), A2 (red), and A3 (brown). Left panel: estimation of ϵ_H by $2\eta\mu_0\langle\mathbf{J} \cdot \mathbf{B}\rangle$. Right panel: scaled ϵ_H with $(\eta/\eta_1)^{-2/3}$ to make decay overlap with each run.

Figure 3. Compensated magnetic energy spectra for simulation runs A1 (left), A2 (middle), and A3 (right) at $t = 5, 6, 7, 9, 12, 16, 21$ (from right to left). Red dot illustrates the spectral peak at each timestep. Horizontal line refers to approximated C_H ($R^2 = 0.99, 0.99$, and 0.96 , respectively).

MHD. We also did simulations for multiple resolutions to measure the uncertainty caused by mesh resolution.

First of all, we examine the helicity dissipation decay of each run. In Figure 2, we plot ϵ_H versus time for simulation subset A as an illustration. We see that ϵ_H levels off at late times, but we find the asymptotic values tend to decrease with decreasing values of η . We can make the curves approximately overlap by scaling them with $(\eta/\eta_{-4})^{0.6}$ (Figure 2b). Here, we have chosen to normalize by $\eta_{-4} = 10^{-4}$, the value of one for A1. It is clear that the magnetic energy spectrum does not follow a universal decay law, and that the magnetic helicity dissipation is mostly controlled by $\eta\langle\mathbf{J} \cdot \mathbf{B}\rangle$ and the system is within the same range of physical control parameters.

In all cases, the nondimensional coefficient C_H in Equation (1) can be estimated by fitting a power law to the spectrum peak at an selected iterative timesteps during inverse cascade (Frisch et al. 1975). The position of the spectral peak is calculated using $k_p = 1/\xi_M$. Note that here and in Equation (8), we have chosen to define ξ_M without a 2π factor.

During the initial phase of each simulation, nonlinear interactions remain underdeveloped, and the energy spectrum is predominantly influenced by initial conditions or external forcing. To ensure that energy transfer to larger scales operates efficiently, we exclude the early times from our analysis. Similarly, at later stages when energy accumulates at the largest available scales, there are constraints imposed by finite domain size, potentially leading to artificial damping of large-scale modes through numerical viscosity or boundary effects. Consequently, we also need to exclude time steps occurring after the cessation of efficient energy transfer. Manual selection of the intermediate stage where energy cascade dominates introduces potential complications and subjective bias. In practice, we implement a systematic logarithmic sampling strategy, retaining snapshots at times corresponding to powers of two in addition to the initial time step. We systematically vary the starting time step from $t = 0$ and fit the corresponding spectral peaks using Equation (1). The configuration yielding the highest coefficient of determination (R^2) is selected to determine

the final value of C_H . R^2 is defined as

$$R^2 = 1 - \frac{\sum_i (E_M(k) - E_M^{\text{fit}}(k))^2}{\sum_i (E_M(k) - \langle E_M(k) \rangle)^2} \quad (14)$$

where $E_M(k_i)$ are the numerical data points retrieved from each simulation, $E_M^{\text{fit}}(k_i)$ the corresponding fit values, and $\langle E_M(k) \rangle$ their mean. R^2 measures the fraction of the variance in the data explained by the fit, with $R^2 = 1$ corresponding to a perfect fit.

We further illustrate the validation of C_H by plotting the compensated magnetic energy spectra

$$E_M^{\text{comp}}(k) = k \epsilon_H^{-2/3} E_M(k). \quad (15)$$

This is shown in Figure 3 for simulation subset A. We see that the second peak evolves underneath an approximately flat envelope, whose value allows us to read off directly the value of C_H in each spectrum. We further obtained an error bar for each simulation run by setting the lowest and highest compensated spectrum peaks as the upper bound and lower bound.

Next, with the fitted C_H in each run, we examine the dependence of C_H with respect to Lu . We enabled larger forcing numbers to generate simulations with larger Lundquist number Lu . In Fig. 4, we show the C_H dependence of Lu for the mesh points $N^3 = 256^3$, 512^3 and 1024^3 . The simulations show that the ratio C_H scales with Lu

$$C_H \propto p \text{Lu}^q, \quad (16)$$

but the exponent is not always the same. For $N^3 = 256$, we find $q \approx 1.11$ for both small and large values of Lu , while for $N^3 = 512$ and $N^3 = 1024$, we find $q \approx 1.18$ and $q \approx 0.69$.

Substituting Lu into the energy spectrum yields

$$E_M(k, t) = v_A^{q+4/3} \eta^{2/3-q} k_f^{2/3-q} k^{-1}. \quad (17)$$

Given that the exponential factor consistently approaches unity, we impose the constraint $q = 1$ and perform a single-parameter fit for the coefficient p . With this constraint applied to the $N = 1024$ simulation data, we obtain $p \approx 0.24$ with a coefficient of determination $R^2 = 0.82$ (Figure 4). The lower resolution cases demonstrate improved agreement with this scaling law, yielding $p \approx 0.23$ for both the $N = 256$ and $N = 512$ configurations, with corresponding R^2 values of 0.90 and 0.98, respectively. This enhanced correlation at lower resolutions suggests that finite-size effects may influence the scaling behavior at higher grid densities.

Although the choice of q does not affect the dimensional ground, a special choice of $q = 2/3$ would yield meaningful results as discussed earlier in introduction.

Figure 4. Dependence of the C_H on Lundquist number Lu for $N = 1024$ simulations of power 1 (solid black line) and power $2/3$ (dashed black line). Each point refers to a simulation run of resolution 1024 (red dot), 512 (red diamond), and 256 (red cross). Solid vertical line refers to error bar estimates.

Similarly, we perform a single-parameter fit for the coefficient p . We apply a similar single-parameter fitting procedure to determine the coefficient p . For $N = 1024$ simulation data, we obtain $p \approx 0.65$ with a coefficient of determination $R^2 = 0.84$ (Figure 4). The lower resolution cases yield a coefficient of $p \approx 0.66$ and $p \approx 0.58$ for the $N = 256$ and $N = 512$ configurations, with corresponding R^2 values of 0.80 and 0.90, respectively. Thus, from a purely empirical point of view, the case $q = 1$ may be quite convincing and deserves to be further investigated.

One might be worried that these results are artifacts of the Lu still being too small and not yet in the asymptotic regime in which a true Lu -independence might be expected. However, by comparing the energy spectra in at least some of the cases with larger forcing wavenumbers indicates that there is indeed a range of $\text{Lu} = 4$ to $\text{Lu} = 50$ in which there is an approximate p scaling. On the other hand, however, we notice that with a larger forcing wavenumber, the estimated C_H tends to be larger with the same Lu condition, i.e., they tend to produce simulation points at the upper left in Figure 4. This may also be regarded as evidence that none of the present simulations are yet in the truly asymptotic regime. Therefore, even higher resolution simulations at larger Lundquist numbers remain essential.

Next, we examine the dependence of C_H with respect to the forcing wavenumber k_f . Subsets B, C, and D exhibit consistency with other characteristic indicators such as Lu and Pr_M , making them suitable for investi-

Figure 5. Dependence of the C_H on forcing wavenumber k_f for simulation subset B (red dots and dashed black line), C (red diamonds and solid black line), and D (red cross and dot black line). Solid vertical line refers to error bar estimates.

gating the effects of varying k_f . We exclude runs in the subset with $k_f/k_1 = 200$ since they tend to be less accurate, i.e., they yield a relatively low R^2 and wider error bars. Similarly, to determine the functional dependence, we fit the relationship $C_H \propto p k_f^q$. Figure 5 shows the fitted curves for all three subsets. The exponent q remains small across all cases, with proportionality coefficients of 5.61, 2.61, and 0.27 for subsets B, C, and D, respectively. While the fitted curves achieve relatively high R^2 scores, the corresponding p -values, i.e., the probability of observing such data under the null hypothesis of no relationship, are elevated to 0.41, 0.39, and 0.03. Since these values exceed the two-sided significance threshold of 0.025 (2.5%), the relationships are statistically insignificant, although the case with $p = 0.03$ (subset D) is only marginally above this threshold. Therefore, we find no robust evidence for a clear dependence between C_H and k_f .

4. CONCLUSIONS

In the present work, we investigated the nondimensional coefficient C_H in the magnetic energy spectrum of magnetically forced helical MHD. We numerically conducted 25 simulations varying multiple characteristics values $\eta k_1/c_s$, k_f/k_1 , N^3 , Pr_M , and Lu . For each run, we scaled η and observed a clear inverse cascade process in the magnetic energy spectrum. We then fitted C_H using a systematic logarithmic sampling strategy and computed the compensated spectrum by $k \epsilon_H^{-2/3}$ to obtain an error estimation.

We extended our findings by investigating Lu dependence of C_H to the regime of high and low Pr_M and

multiple resolutions. Based on dimensional analysis, we tested two potential dependencies. Our results confirm that C_H obeys a linear dependence on Lu ; the single-parameter fit for the coefficient is 0.24 with a coefficient of determination $R^2 = 0.82$. We also find that C_H potentially obeys a power dependence on Lu with a power $2/3$, and the single-parameter fit for the coefficient is 0.65 with a coefficient of determination $R^2 = 0.84$. This dependence is not affected by Pr_M and η in the current range investigated. Furthermore, we investigated k_f dependence of C_H and found no clear statistical correlation between those two values.

For many astrophysical systems, the microscopic energy dissipation mechanism is not of Spitzer type, as assumed here, and the significance of Lu is unclear. It is not obvious how this would affect our results. It is probably true that a suitable value of Lu can be defined based on the growth rate of microphysical plasma instabilities. In any case, it is clear that conclusions based on C_H have a linear dependence on the Lundquist number.

Though it turns out that for large magnetic Prandtl numbers, most energy is dissipated viscously rather than resistively (Brandenburg 2014), a significant amount of energy could be dissipated resistively, especially when the magnetic energy strongly dominates over kinetic, for example in local accretion disk simulations (Brandenburg et al. 1995).

Our present work motivates possible avenues for future research. First, it highlights the significance of examining energy dissipation in astrophysical fluid dynamics, which is often ignored since most astrophysical fluid codes rely entirely on numerical prescriptions needed to dissipate energy when and where needed. In some extreme cases, for example, at very small values of Pr_M , most of the energy is dissipated through resistivity rather than viscous dissipation, which fundamentally alters the energy cascade dynamics. While kinetic energy dissipation still occurs at small scales through viscous processes, the dominant energy dissipation pathway shifts to magnetic diffusion, making the inverse cascade in the magnetic energy spectrum a crucial mechanism that affects the overall energy dissipation in the system.

A critical verification requirement for describing the asymptotic regime is to confirm the independence of C_H from Lu across an extended range of parameter combinations. Given the inherent limitations imposed by finite numerical resolution, rectangular computational domains may still provide a viable approach to accessing a broader spectrum of spatial scales (Brandenburg et al. 2024). Additional strategies include implementing time-dependent profiles for η and ν to achieve greater scal-

ing with Pr_M and separation between forcing wavenumber k_f . However, such modifications introduce potential numerical artifacts that require rigorous validation. Care must be taken to distinguish physical phenomena from computational artifacts, particularly when employing hyperviscosity and hyperresistivity techniques, which are commonly utilized in MHD simulations, but may introduce poorly understood numerical effects that could compromise the physical interpretation of results.
